## Background

Hemophilia A (HA), a genetic coagulation factor VIII deficiency, commonly causes spontaneous bleeding. Recombinant human factor VIII (rhFVIII) is administered to treat bleeding in HA human patients, but was not reported in hemophilic dogs.

## Case presentation

A 7-year old intact male poodle dog was admitted with marked oral hemorrhage of 4-days duration. HA was diagnosed 3 years before (5% factor VIII activity), and the dog was previously hospitalized several times due to significant bleeding episodes and was treated with pRBC and FFP. Two months prior, loose molar and pre-molar teeth were extracted due to severe ongoing gingival hemorrhage and dental disease, and major intra- and post-operative hemorrhage occurred despite pre-operative cryoprecipitate, tranexamic acid (TXA) and desmopressin treatment, requiring 4 FFP units and 1 packed RBC unit post-op.

Physical examination showed pale mucous membranes, marked gingival hemorrhage, tachycardia and a left apical systolic murmur. PCV was 21% (reference interval 37-55%). Oral examination under anesthesia revealed bilateral oronasal fistulas in both maxillary teeth. Due to ongoing bleeding, dental extractions were planned.

Treatment: immediately prior to induction, an IV bolus of rhFVIII (Advate®, 1000 IU, Baxter AG, Austria, 5 mg/kg, Figure 4) was administered, followed by a 20-hour IV constant rate infusion (CRI; at 4 mg/kg/hour). TXA was administered upon induction (30 mg/kg slow IV, followed by 3-hour CRI at 30 mg/kg/hour). During the procedure 5 teeth were extracted (2 canine, 2 premolar, 1 incisor), 1 unit of matched pRBC was administered, and absorbable gelatin foam was locally placed.

Thromboelastometry (TEM), performed prior to treatment, revealed intrinsic-pathway hypocoagulability (Figure 1a), typical of HA, with compensatory extrinsic hypercoagulability (Figure 1b), which improved upon repeated TEM, 4 and 12 hours post commencing rhFVIII therapy (Figures 1c-f and Figure 2). Citrated plasma samples from the dog and 2 control dogs taken before, during and after treatment were sent to a human laboratory for quantification of factor VIII activity; however, failed to document a measurable increase (Figure 3).

The dog recovered uneventfully, with no evidence of bleeding, and was discharged 36 hours post initial therapy with rhFVIII

## New or Unique information:

This first report of successful treatment with human-recombinant factor VIII for Hemophilia A induced clinical bleeding supports this therapy in hemophilic dogs.
